We report on the magnetoresistance (MR) and electron transport measurements observed on a single crystal magnetite nanowire prepared using a hydrothermal synthesis method. Highresolution electron microscopy revealed the single crystal magnetite nanowires with 80–120 nm thickness and up to  $8 \mu m$  in length. Magnetic measurements showed the typical Verwey transition around 120 K with a 100 Oe room temperature coercivity and 45 emu/g saturation magnetization, which are comparable to bulk magnetite. Electrical resistance measurements in 5–300 K temperature range were performed by scanning gate voltage and varying applied magnetic field. Electrical resistivity of the nanowire was found to be around  $5 \times 10^{-4} \Omega$  m, slightly higher than the bulk and has activation energy of  $0.07 \text{ eV}$ . A negative MR of about  $0.7\%$  is observed for as-synthesized nanowires at 0.3 T applied field. MR scaled with increasing applied magnetic field representing the field-induced alignment of magnetic domain. These results are attributed to the spin-polarized electron transport across the antiphase boundaries, which implicate promising applications for nanowires in magnetoelectronics.  $\odot$  2015 AIP Publishing LLC. [[http://dx.doi.org/10.1063/1.4914535\]](http://dx.doi.org/10.1063/1.4914535)

Being part of the Half-metal family, magnetite  $(Fe<sub>3</sub>O<sub>4</sub>)$ has been the subject of research focus recently due to its potential applications in magnetoelectronics. $1-3$  Magnetite is predicted to display a 100% spin polarization at the Fermi level, with majority spin electrons exhibiting insulating or semiconducting behavior, while the minority spins showing metallic behavior.<sup>[2](#page-4-0)</sup> Unusually high Curie temperature (858 K) of  $Fe<sub>3</sub>O<sub>4</sub>$  facilitates device integration at room temperature for magneto-electronic applications. Bulk and polycrystalline magnetite was found to have more than 10% magnetoresistance  $(MR)$ ,<sup>[4,5](#page-4-0)</sup> which is still far below the theoretical prediction. The observed MR is attributed to spin polarized electron injection through tunnel barriers, grain boundaries, and interparticle contacts.<sup>[6,7](#page-4-0)</sup> Defects, reconstruction at the surface and interfaces, strain effects, and off-stoichiometry reduce the spin-polarized current.<sup>[8](#page-4-0)</sup> Material microstructure, coercivity, grain size, grain boundary structure, and crystallite orientations define the intrinsic properties of magnetite for spintronics applications.<sup>[2](#page-4-0)</sup> Unprecedented technology advancements in miniaturizing the device integration are driving the research at nanoscale. MR and electron transport studies on magnetite were largely focused on thin films, bulk, nanocrystal assemblies, and compact powder forms. $2,4,9-11$  Shape anisotropy and the low-dimensionality of nanostructures play critical role in determining the spin transport properties. However, there are very few reports in the literature focusing magnetotransport on the magnetite nanostructures.

One-dimensional (1D) nanostructures have unique electron transport properties compared to bulk and have shown potential applications in nanodevice electronics. Several attempts were made by researchers to understand the magnetic and electronic properties of 1D  $Fe<sub>3</sub>O<sub>4</sub>$  nanowires. Liu et  $al$ <sup>[12](#page-4-0)</sup> studied the magnetotransport in individual single crystal magnetite nanotube and observed a negative 1% MR at 77 K and 0.7 T applied field. Magnetic microstructure of 1D  $Fe<sub>3</sub>O<sub>4</sub>$  nanowires was studied by mapping the magnetic flux by electron holography<sup>[13](#page-4-0)</sup> suggesting the possibility of regulating spin current, apart from understanding the magnetic behavior using SQUID magnetometer. Epitaxially grown  $MgO/Fe<sub>3</sub>O<sub>4</sub>$  core shell nanostructures were found to have 1.2% MR at room temperature under 1.8 T applied field, which is credited to the tunneling of spin-polarized electrons across the antiphase boundaries.<sup>[14](#page-4-0)</sup> Terrier *et al.* measured the transport properties of several polycrystalline nanowires and reported 8.5% MR at room temperature and did not observe any anisotropy[.15](#page-4-0) The magneto-electron transport properties of an individual single crystalline  $Fe<sub>3</sub>O<sub>4</sub>$ nanowire are still inconsistent. All the aforementioned studies attribute the MR response to tunneling of spin-polarized electrons across grain boundaries or interparticle contact. However, it would be interesting to study the MR using a single crystalline nanowire eliminating the interparticle contacts and grain boundaries. To this effect, Liao et al. have observed an anomalous 7.5% positive MR on individual magnetite nanowire, and the device demonstrated a spin-filter effect, prepared through hydrothermal method.<sup>[16](#page-4-0)</sup> But, unusual positive  $MR^{16}$  $MR^{16}$  $MR^{16}$  observation in single crystal nanowire is contradicting the negative MR observed with epitaxial thin films, bulk and polycrystalline  $Fe<sub>3</sub>O<sub>4</sub>.<sup>2,4,14,17,18</sup>$  $Fe<sub>3</sub>O<sub>4</sub>.<sup>2,4,14,17,18</sup>$  $Fe<sub>3</sub>O<sub>4</sub>.<sup>2,4,14,17,18</sup>$  In this report, we discuss the magneto-electron transport properties from a single crystalline magnetite nanowire that exhibits negative MR.

<span id="page-2-0"></span>Single crystal  $Fe<sub>3</sub>O<sub>4</sub>$  nanowires were prepared by a simple hydrothermal method. In a typical process, FeSO<sub>4</sub>,  $Na<sub>2</sub>S<sub>2</sub>O<sub>3</sub>$ , and NaOH are mixed in 2:1:25 molar ratio and ground thoroughly. The mixture is then transferred to a Teflon lined autoclave containing polyethylene glycol (molecular weight—4000) in water (3:1). The autoclave is subjected to heat treatment at  $160^{\circ}$ C for 24 h and cooled to room temperature naturally. The contents are washed with water and ethanol to remove the polymer residue and vacuum dried. The samples were probed with X-ray diffractometer (Sintag XDS 2000), scanning electron microscopy (Sirion), high resolution transmission electron microscopy (Tecnai 200KV), and Quantum design SQUID magnetometer (0–7 T, 5–300 K). A solution containing  $Fe<sub>3</sub>O<sub>4</sub>$  nanowires in ethanol is dropped onto to a 500 nm  $SiO<sub>2</sub>/Si$  substrate wafer and allowed it to dry under inert atmosphere.  $Fe<sub>3</sub>O<sub>4</sub>$  nanowire (120 nm thickness) device with 3  $\mu$ m channel length was fabricated using electron beam lithography and a 5 nm/ 100 nm thick Ti/Au electrodes were deposited using electron beam deposition.

X-ray diffraction data collected on as synthesized nanowire powder confirmed cubic magnetite  $(F_{2}O_{4})$  phase purity matching the JCPDS index card 79–0416 (not shown here). A small degree of a polymer residue and a second cubic magnetite phase is observed in XRD spectra. Electron microscopy analyses were performed to understand morphology, microstructure, and crystalline phase of the nanowires. Scanning electron microscopy image, Figure  $1(a)$ , shows representative  $Fe<sub>3</sub>O<sub>4</sub>$  nanowires with 80–120 nm thickness and lengths up to 8  $\mu$ m with uniform morphology. A small percentage of  $Fe<sub>3</sub>O<sub>4</sub>$  discs and polymer remainder were also observed along with the nanowires. Selected area electron diffraction (SAED) pattern showed the discs to be of cubic

FIG. 1. Electron microscopy images showing Fe<sub>3</sub>O<sub>4</sub> nanowires. (a) SEM image of  $Fe<sub>3</sub>O<sub>4</sub>$  nanowires and discs morphology, (b) TEM images showing clean Fe<sub>3</sub>O<sub>4</sub> nanowires, (inset) SAED pattern corresponding to Fe<sub>3</sub>O<sub>4</sub>, (c) TEM image of single nanowire, (inset) high resolution image without any defects, collected from the red circle region, (d) high resolution micrograph showing clean  $Fe<sub>3</sub>O<sub>4</sub>$  without any surface reconstruction or impurities, (inset) FFT image showing zone axis  $[-121]$ .

 $Fe<sub>3</sub>O<sub>4</sub>$  phase (JCPDS index card 88-0866). High resolution transmission electron microscopy images in Figures 1(b) and 1(c) reveal morphology and highly crystalline microstructure of as prepared nanowires. SAED pattern inset, Figure 1(c), collected on few nanowires can be indexed to the cubic magnetite phase. It can be seen that SAED pattern of nanowires conforms well to that of XRD pattern. HRTEM image in Figure 1(d) collected from 80 nm wide single nanowire shows single crystalline nature of nanowire and possibly shows growth defects that can be related to antiphase boundaries. It can be realized that the core and surface of nanowire are well preserved and a Fast Fourier Transform (FFT) analysis shown in Figure  $1(d)$  inset reveals the diffraction planes for single crystal magnetite nanowire. The analyzed zone axis for electron diffraction pattern for nanowire is  $[-121]$  and the diffraction spots were indexed to  $(220)$ ,  $(311)$ , and  $(111)$  lattice planes of Fe<sub>3</sub>O<sub>4</sub>. Electron microscopy results show a very low percentage of defects and clearly establish the single crystallinity of the  $Fe<sub>3</sub>O<sub>4</sub>$ nanowires.

Magnetic properties of single crystal  $Fe<sub>3</sub>O<sub>4</sub>$  nanowires were evaluated using a SQUID magnetometer. Room temperature magnetic hysteresis was collected on nanowire powder sample without any preferred orientation of magnetic field. A saturation magnetization  $(M_s)$  of about 45 emu/g, 100 Oe coercivity, and a remanence magnetization  $(M_r)$  of 6.2 emu/g were observed for randomly oriented single crystal nanowire samples, as shown in Figure  $2(a)$  indicating room temperature ferromagnetism. Figure  $2(a)$  inset shows clear coercivity and remanent magnetization confirming ferromagnetism. The observed saturation magnetization is comparable to that of bulk and higher than other  $Fe<sub>3</sub>O<sub>4</sub>$ nanocrystalline samples.<sup>[19](#page-4-0)</sup> Orientation of nanocrystallites, crystallinity, shape anisotropy, defects, and magnetostatic coupling are the key factors influencing saturation magnetization and other magnetic properties. $20,21$  Magnetic susceptibility measurements were carried out on the  $Fe<sub>3</sub>O<sub>4</sub>$ nanowires to study possible phase transitions associated with temperature (5–300 K) and magnetic field dependence. Figure [2\(b\)](#page-3-0) shows zero-field cooled (ZFC) and field cooled (FC) magnetization for  $Fe<sub>3</sub>O<sub>4</sub>$  nanowires with a 100 Oe applied magnetic field. With increasing temperature, the magnetization reaches a maximum value around 120 K for ZFC/FC measurements, which is defined as blocking temperature  $T_B$  in bulk Fe<sub>3</sub>O<sub>4</sub>, where the thermal energy becomes comparable to the anisotropy energy barrier. Below  $T_B$ , magnetization of the nanowires aligns with the easy axis and anisotropy energy barriers would minimize magnetic moment with decreasing temperature. Above  $T_B$ , thermal energy overcomes the anisotropy and magnetic moments are aligned in the direction of external field. Blocking temperature is widely dependent on the magnetic interactions, morphology, and external agents.<sup>[22](#page-4-0)</sup> Above  $T_B$ , such "superparamagnetic" particles are expected to display zero coercivity and the FC and ZFC magnetizations will become identical. The clearly open hysteresis loops observed in our samples at  $T > T_B$  (see data at 300 K shown in Fig. [2](#page-3-0)) and the continued divergence of FC and ZFC magnetizations for  $T > T_B$  region suggest that 120 K is not a blocking temperature. The observed

<span id="page-3-0"></span>

FIG. 2. Magnetization measurements collected on a bunch of  $Fe<sub>3</sub>O<sub>4</sub>$  nanowires. (a) Room temperature hysteresis showing a 45 emu/g  $M_s$ , 6.2 emu/g  $M_r$ , and  $\sim$ 100 Oe coercivity. (Inset) An expanded hysteresis view to show the low field region, displaying coercivity. (b) Zero-field cooled and field cooled magnetization studies in 5 K–300 K regime at a 100 Oe applied field. Verwey transition can be visualized around 120 K.

magnetization change at 120 K can be explained with Verwey transition.<sup>[23,24](#page-4-0)</sup> According to Verwey transition,  $Fe<sub>3</sub>O<sub>4</sub>$  undergoes a charge ordering and structural ordering in the crystal lattice with crystallographic phase changing from cubic inverse spinel to monoclinic and the electrical properties display a metal-insulator transition as the temperature drops below 120 K. Verwey transition has profound effect on electrical properties of the  $Fe<sub>3</sub>O<sub>4</sub>$ , which is discussed in the later section.

Figure 3 inset shows SEM image of  $Fe<sub>3</sub>O<sub>4</sub>$  nanowire device fabricated using e-beam lithography. Electrical measurements performed in ambient conditions on the nanowire yielded a typical linear I-V curve showing Ohmic behavior for device. Figure 3 shows resistance from a single nanowire as a function of temperature in the 5–300 K regime at a constant voltage bias. The circles represent resistance (R) data points acquired from original I-V scans and the line represents best fit. Electrical resistance of single Fe<sub>3</sub>O<sub>4</sub> nanowire at room temperature is around  $5 \times 10^{-4} \Omega$  m, which is comparable to epitaxial thin films<sup>14,25</sup> and higher than bulk single crystal  $Fe<sub>3</sub>O<sub>4</sub>$ .<sup>[26](#page-4-0)</sup> Electrical resistance below 120 K is almost 2 orders of magnitude higher compared to room temperature. Above 120 K, the resistance decreased, which is in accordance with

FIG. 3. Electrical resistance (left) measurements on a single  $Fe<sub>3</sub>O<sub>4</sub>$  nanowire with temperature variation recorded at a constant voltage bias. Below 120 K (Verwey transition), the resistivity increased by 2 order of magnitude, while above  $120$  K a conducting behavior is observed. (Right)  $ln(R)$  vs  $1000/T$  plot showing the activation energy around 0.07 eV. Inset shows a representative 120 nm thick Fe<sub>3</sub>O<sub>4</sub> nanowire device with 3  $\mu$ m channel length.

the Verwey transition. Above 120 K, Arrhenius plot shows linear relation, signifying thermally activated carrier transport mechanism at higher temperature. Activation energy (ln R vs 1000/T) deducted from Figure 3 is around 0.07 eV. This value is in close agreement with similar morphology  $Fe<sub>3</sub>O<sub>4</sub>$  nanowire/nanotube studies as well as bulk  $Fe<sub>3</sub>O<sub>4</sub>$ .  $12,14,27$ 

Figure 4 shows 300 K MR measurements on a single crystal Fe3O4 nanowire device. Magnetic field is swept parallel to the nanowire from 0 to 0.3 T, keeping a constant voltage bias at a selected temperature. MR is calculated using equation,  $MR = [R(H) - R(0)]/R(0)$ , where R(0) and R(H) are resistance at zero field and at an applied field H, respectively. A total of 3 devices were tested and the value varied from  $-0.2\%$  to  $-0.7\%$  at a 0.3 T applied field. MR of Fe<sub>3</sub>O<sub>4</sub> nanowires increased with applied magnetic field and did not show any saturation. A linear background is subtracted from measurement, as the actual MR signal was small. MR studies

FIG. 4. Room temperature magnetoresistance plot showing a  $-0.7\%$  MR at  $0.3$  T magnetic field collected from the single crystal Fe<sub>3</sub>O<sub>4</sub> nanowire.

<span id="page-4-0"></span>in single crystal  $Fe<sub>3</sub>O<sub>4</sub>$  are quite inconsistent compared to that of bulk. Liao et  $al$ .<sup>16</sup> reported anomalous positive MR  $\sim$ 7.5% in single crystal Fe<sub>3</sub>O<sub>4</sub> nanowire, while Coey *et al.*<sup>2</sup> did not see any measurable MR in a single crystal  $Fe<sub>3</sub>O<sub>4</sub>$ . On the contrary, a negative MR is observed in this work. MR in the polycrystalline  $Fe<sub>3</sub>O<sub>4</sub>$  is credited to magnetization in ferromagnetic grains, which are exchange-decoupled, or antiphase domains.<sup>2</sup> Considering the fact that the single crystal  $Fe<sub>3</sub>O<sub>4</sub>$  nanowire is 120 nm thick there is a strong possibility for huge density of antiphase domain walls to be present. HRTEM (Figure  $1(d)$ ) possibly shows the antiphase domains present in the nanowire. The resulting magnetic coupling between antiphase boundaries is antiferromagnetic. $28-30$ When an external magnetic field is applied, neighboring antiphase boundary magnetic moment aligns in the direction of the field, resulting in reduced resistance. The absence of resistance saturation in  $Fe<sub>3</sub>O<sub>4</sub>$  nanowire indicates the strong antiferromagnetic coupling of antiphase boundaries. Spinpolarized transport across antiphase boundaries in single crystal is analogous to epitaxial films, resulting in MR.

In summary, we demonstrated single crystal  $Fe<sub>3</sub>O<sub>4</sub>$ nanowire showing a small but definite negative magnetoresistance at room temperature and attributed to the spinpolarized current resulting from antiphase domains. Nanowires were synthesized by a hydrothermal method and high resolution electron microscopy revealed cubic single crystalline magnetite. Room temperature electrical measurements have shown a resistance of  $\sim 5 \times 10^{-4} \Omega$  m on single nanowire and activation energy of 0.07 eV. Magnetic saturation and coercivity of  $Fe<sub>3</sub>O<sub>4</sub>$  were found to be 45 emu/g and 100 Oe, respectively, at 300 K consistent with reported values for bulk  $Fe<sub>3</sub>O<sub>4</sub>$ . Inconsistent magnetoresistance properties from Fe<sub>3</sub>O<sub>4</sub> single crystal nanowire are still debatable and needs further research attention. Our work demonstrates the experimental evidence of negative MR in  $Fe<sub>3</sub>O<sub>4</sub>$  single crystal nanowires suggesting that spin based device integration can be realized.
