Abstract

The aerodynamic roughness length (Z_{0m}) serves an important role in the flux exchange between the land surface and atmosphere. In this study, airborne lidar (ALS), terrestrial lidar (TLS), and imaging spectroscopy data were integrated to develop and test two approaches to estimate Z_{0m} over a shrub dominated dryland study area in south-central Idaho, USA. Sensitivity of the two parameterization methods to estimate Z_{0m} was analyzed. The comparison of eddy covariance-derived Z_{0m} and remote sensing-derived Z_{0m} showed that the accuracy of the estimated Z_{0m} heavily depends on the estimation model and the representation of shrub (e.g., *Artemisia tridentata* subsp. *wyomingensis*) height in the models. The geometrical method (RA1994) led to 9 percent (~ 0.5 cm) and 25% (~ 1.1 cm) errors at site 1 and site 2, respectively, which performed better than the height variability-based method (MR1994) with bias error of 20 percent and 48 percent at site 1 and site 2, respectively. The RA1994 model resulted in a larger range of Z_{0m} than the MR1994 method. We also found that the mean, median and 75th percentiles of heights (H75) from ALS provides the best Z_{0m} estimates in the MR1994 model, while the mean, median, and MAD (Median Absolute Deviation from Median Height), as well as AAD (Mean Absolute Deviation from Mean Height) heights from ALS provides the best Z_{0m} estimates in the RA1994 model. In addition, the fractional cover of shrub and grass, distinguished with ALS and imaging spectroscopy data, provided the opportunity to estimate the frontal area index at the pixel-level to assess the influence of grass and shrub on Z_{0m} estimates in the RA1994 method. Results indicate that grass had little effect on Z_{0m} in the RA1994 method. The Z_{0m} estimations were tightly coupled with vegetation height and its local variance for the shrubs. Overall, the results demonstrate that the use of height and fractional cover from remote sensing data are promising for estimating Z_{0m} , and thus refining land surface models at regional scales in semiarid shrublands.

Introduction

The roughness of the land surface plays an important role in the flux exchange between the land surface and atmosphere (Sud *et al.*, 1988; Prueger *et al.*, 2004). Land surface roughness can be characterized by the aerodynamic roughness length (Z_{0m}), which is the height of roughness elements at which the mean wind speed approaches zero given the extrapolation of the logarithmic wind profile (Garratt, 1992; Kaimal and Finnigan, 1994). In dryland ecosystems, such as semiarid shrublands, the spatial distribution of roughness elements and specifically Z_{0m} are key parameters for physical models of aeolian transport and for estimating dust emissions from wind erosion (Prigent *et al.*, 2005; Sankey *et al.*, 2010; Sankey *et al.*, 2013; Nield *et al.*, 2013; Pelletier and Field, 2016) and for land surface models (Dickinson and Henderson-Sellers, 1988; Jasinski and Crago, 1999).

Traditionally, Z_{0m} is calculated using the Monin-Obukhov similarity theory (MOST) applied to measurements of horizontal wind speed profiles (Garratt, 1994; Kustas *et al.*, 1994). Therefore, Z_{0m} can be obtained through observations by an eddy covariance (EC) system which provides meteorological measurements; however, estimating Z_{0m} from EC is restricted to a single value in the source area of the EC tower, and thus EC estimates are limited for regional land surface models (Paul-Limoges *et al.*, 2013). To address this issue, studies have used remotely sensed information, such as scatterometer (Prigent *et al.*, 2005) and bi-directional reflectance (Marticorena *et al.*, 2004) data, along with laser altimeter measurements (Menenti and Ritchie, 1994; De Vries *et al.*, 2003; Colin and Faivre, 2010; Weligepolage *et al.*, 2012) for parameterizing Z_{0m} over a local or regional scale. Aerodynamic roughness is influenced by the height, geometry, density and pattern of roughness elements which include vegetation and micro- and macro-topographic features (Garratt, 1992; Lettau, 1969; Raupach, 1992 and 1994; Shaw and Pereira, 1982). Empirical relationships between Z_{0m} and measurable characteristics of roughness elements (e.g., vegetation height, normalized difference vegetation index (NDVI), leaf area index (LAI), frontal area index (FAI, λ_p)) have been used to parameterize Z_{0m} over a large scale. For example, NDVI and LAI derived from optical remote sensing have been correlated with Z_{0m} (Choudhury and Monteith, 1988; Bastiaanssen, 1995; Jia *et al.*, 2003). In some previous studies, Z_{0m} was assumed as a proportion of roughness element height (i.e., Kustas *et al.*, 1989; Garratt, 1992). The three-dimensional (3D) structure of the land's surface and vegetation, as captured by laser altimetry (or light detection and ranging (lidar)) provides a straightforward measure of

roughness element height across the landscape. Tian *et al.* (2011) combined lidar-derived forest structural variables (tree height, first branch height, crown width, and stand density) and SPOT5-derived LAI to parameterize Z_{om} in a forested environment. They concluded that Z_{om} estimates derived from lidar are more accurate than those derived from satellite optical remote sensing data. Menenti and Ritchie (1994) computed Z_{om} based on the geometrical regularity of vegetation canopies using lidar-derived vegetation heights (average and standard deviations). This method was adapted by Brown and Hugenholtz (2012) for Z_{om} estimates in a mixed grassland prairie and further assessed by Paul-Limoges *et al.* (2013) in a harvested Douglas-fir forest. Colin and Faivre (2010) estimated Z_{om} based on a geometrical model using lidar-derived height and wind profile information and concluded that the geometrical model could provide comparable results on natural heterogeneous land covers present in the region, including sparse grassland and low tree land cover types.

While some previous studies have demonstrated that lidar is well-suited for deriving Z_{om} (e.g., Brown *et al.*, 2012; Hugenholtz *et al.*, 2013; Paul-Limoges *et al.*, 2013), there are practical limitations of deriving structural information in shrublands from lidar, and in particular airborne lidar. These limitations include underestimation of height and difficulty

in deriving individual roughness element canopies (Hopkinson *et al.*, 2005; Glenn *et al.*, 2011; Mitchell *et al.*, 2012). Variables derived from complementary airborne imaging spectroscopy (aka hyperspectral) data may be necessary, particularly if the combination with lidar is capable of improved vegetation cover estimates (Mitchell *et al.*, 2015), which are relatable to shrub density.

In this paper we develop an optimized processing flow that uses high resolution, remotely sensed optical and 3D datasets to spatially extend Z_{om} mapping over a semiarid landscape dominated by the open canopy, low stature, and sparse vegetation (<25 percent canopy cover). This landscape is representative of approximately 62 million ha of sagebrush steppe in the Great Basin, western US. Resolving differences in Z_{om} at the landscape scale with remote sensing techniques has the potential to improve energy balance estimates in hydrologic and ecologic models in this and similar dryland ecosystems (Allen *et al.*, 2011; Paul *et al.* 2014). Two existing models of estimating Z_{om} were evaluated: the height variability model of Menenti and Ritchie (1994) (hereafter, MR1994) and the wind profile model developed by Raupach (1994) (hereafter, RA1994). We chose these two models amongst those listed in Table 1 because they are suitable for use in sparse vegetation (Menenti and Ritchie, 1994; Raupach, 1994;

Table 1. Common Z_{om} Parameterization Methods with Input Parameters

References	Parameters	Equations	Strength	Weakness
Garratt (1994)	Height	$z_{om} = ah$	The simplest method.	Only height is taken into account.
Lettau (1969)	Height and frontal index	$z_{om} = 0.5h\lambda_f$	Most appropriate in vegetation where the roughness elements are very evenly spaced.	It is not suitable for roughness elements with high density.
Menenti and Ritchie (1994)	Height	$z_{om} = \gamma_N \Sigma [\sigma_{h,i} / h_i] * \bar{h}$	Empirical model.	Only height is taken into account.
Raupach (1994)	Height, frontal index, meteorological measurements	$\frac{Z_{om}}{h_v} = \left(1 - \frac{d_0}{h_v}\right) \cdot \exp\left(-k \frac{U}{u_*} + \phi_h\right)$ $\frac{d_0}{h_v} = 1 - \frac{1 - \exp\left[-(C_{dl} 2 \lambda_f)^{0.5}\right]}{(C_{dl} 2 \lambda_f)^{0.5}}$	For sparse vegetation areas with small topographic relief.	It is complex and needs many input parameters.
Macdonald (1998)	Height and frontal index	$\frac{d}{h} = 1 + a^{-\lambda_f} (\lambda_p - 1)$ $\frac{z_{om}}{h} = \left(1 - \frac{d}{h}\right) \exp\left[-\left(0.5 \beta \frac{C_D}{k^2} \left(1 - \frac{d}{h}\right) \lambda_f\right)^{-0.5}\right]$	For heterogeneous land surface and urban regions; Can explain the direction of airflow.	It is complex and needs many input parameters.
Bastiaanssen (1998)	NDVI	$z_{om} \exp(a + bNDVI)$	Applied at regional scales.	The model has limits on different vegetation types and results sensitive to plant phenology.
Choudhury and Monteith (1988)	LAI, height	$d = h \left[\ln\left(1 + X^{\frac{1}{6}}\right) + 0.03 \ln\left(1 + X^6\right) \right]$ $Z_{om} = \begin{cases} Z_{os} + 0.28hX^{\frac{1}{2}} & \text{for } 0 \leq X \leq 0.2 \\ 0.3h\left(1 - \frac{d}{h}\right) & \text{for } 0.2 < X \leq 2 \end{cases}$ $X = 0.2LAI$	Applied at regional scales.	The model has limits on different vegetation types and results sensitive to plant phenology.

Brown and Hugenholtz, 2012). In addition, the models' input variables are suitable to derive from remote sensing data and subsequently allow us to explore the use of lidar and optical hyperspectral data for estimating aerodynamic roughness length. MR1994 is an empirical model and can be implemented by utilizing the roughness element height and its standard deviation. The RA1994 is a geometrical model based on the wind velocity profile and accounts for height and density of roughness elements (FAI, discussed in more detail below). Our objectives were to (a) explore an optimal Z_{om} estimation model for the shrub-steppe landscape studied herein; (b) quantify the sensitivity of the main driving parameters in the Z_{om} estimation models; and (c) evaluate the potential advantages and limitations of integrating lidar and imaging spectroscopy data for parameterizing Z_{om} over a larger, regional area.

Experimental Site and Data

Site Description

The study site is located southwest of Hollister, Idaho ($42^{\circ}19'26.56''N$, $114^{\circ}42'3.29''W$). The site was bound on either end by a scintillometer transmitter and receiver, and between them at even spacing were two eddy covariance (EC) stations (Figure 1). The plant community consists primarily of Wyoming Big Sagebrush (*Artemisia tridentata* ssp *wyomingensis*) with an understory of native grasses and cheatgrass (*Bromus tectorum*). The sagebrush heights range from 0.01 to 1 m with mean (SD) of 0.11 m (0.04 m). Soils are shallow and are interspersed with basalt rocks (not protruding more than a few to 10 cm above ground). The elevation ranges from 1,410 to 1,450 m with a mean of 1,426 m and standard deviation of 9.5 m. The sagebrush canopy cover is relatively homogenous with 25 percent mean shrub cover (derived from hyperspectral and lidar, see below) at a several m^2 scale across the 1 to 2 km transect.

Meteorological Data

Measurements from the two EC flux towers such as wind direction and speed, and sensible heat flux have been collected every half-hour since 2009. Meteorological measurements have been collected with several 3D sonic anemometers dispersed across the footprint (turbulent source area) (RMYoung and CSAT). In addition, the site was instrumented in several locations to collect measurements of soil moisture, temperature, and heat flux. Meteorological measurements collected over two time frames were used for *in-situ* Z_{om} calculation and source area analysis. Z_{om} was estimated on 05, 06, and 14 August 2010, corresponding to the lidar and imaging spectroscopy data collection. A multi-year period (2009 to 2010) was also used to provide an average estimate of Z_{om} over a longer timeframe. The analysis over this period assumed limited shrub growth, typical of sagebrush-dominated regions (e.g., Watts and Wambolt, 1996). The original 20 Hz binary EC data were subjected to QA/QC (Quality Assurance and Quality Control) procedures that included sufficient power for instrument operation (>10 V); erroneous measurements disrupted by raindrops; wind direction from the backside of the CSAT3 sonic anemometers; removal of outlier data identified by comparing data from multiple co-located sensors, and spike removal. The EC data were adjusted to synchronize data from different types of sensors, using coordinate rotation of 3D wind data (Lee *et al.*, 2004) and correction of density effects on sensible and latent heat transfer (Webb *et al.*, 1980). The final samples of EC data were used to determine Z_{om} under stable, unstable, and near-neutral conditions.

Remote Sensing Data

In this paper, remote sensing data include airborne lidar (ALS), terrestrial laser scanning (TLS) and imaging spectroscopy data. (see Table 2). Lidar was used to derive the height-related information for the roughness elements (shrub and grass vegetation) and the digital elevation model (DEM). The hyperspectral data were combined with lidar for estimating percent cover of the roughness elements, which is approximate to the roughness element density and can be used for the frontal area index (FAI) calculation. TLS data were also collected to calibrate the underestimation of vegetation height by ALS. Heights from TLS have been shown to have a nearly perfect agreement with field-measured sagebrush heights due to the ground-based collection method of TLS (Li *et al.*, 2015). Small footprint ALS data were acquired using a dual-mounted Leica ALS50 Phase II sensor onboard a Cessna Caravan 208B operated by Quantum Spatial, Inc., Corvallis, Oregon. The lidar data were collected on 05 and 06 August 2010, using a wavelength of 1064 nm and a resultant average point density of 7 points per m^2 . The TLS data were collected in the near infrared (1550 nm) with a Riegl VZ-1000 (Riegl, Horn, Austria) instrument with a scan range of approximately 1 km and a beam divergence of 0.3 mrad. The TLS data were collected in fall 2011 and 2012. Six plots, 30 m by 30 m each, were established and scanned using a TLS positioned on a tripod 2 m above the ground. Imaging spectroscopy data were collected 14 August 2010, with the HyMap sensor (operated by HyVista, Inc., Sydney, Australia), which collects calibrated radiance data in 126 near-contiguous spectral bands (450 - 2480 nm) that range in

width from 15 μm in the visible and near infrared to 20 μm in the shortwave infrared (Cocks *et al.*, 1998) at a pixel resolution of 3.125 m by 3.125 m.

Table 2. Remote Sensing and Eddy Covariance Data Sets Used in the Study

Data sets	Acquisition Date	Characteristics
Terrestrial lidar	Sept. 2011 and 2012	Average point density of 10,000 points per m^2 at six plots, each 30 m by 30 m. Scanning occurred from a 2 m tripod.
Airborne lidar	05 and 06 Aug 2010	Average point density of 7 points per m^2
Hyperspectral	14 Aug 2010	3 m resolution, 450-2500 nm wavelengths
Eddy Covariance	05, 06 and 14 Aug 2010	RMYoung and CSAT sensors Site 1: Main wind direction: 173° Main wind speed: 5.2 m/s Site 2: Main wind direction: 183° Main wind speed: 5.3 m/s

Methods

In our study, FAI and vegetation heights are the main variables derived from the remotely sensed data for Z_{om} estimation. The percent cover of vegetation (PVC) that represented the cover percentage of roughness elements was derived from a combination of lidar and imaging spectroscopy data and then used for FAI calculation. In order to test the sensitivity of height in the models, a range of different height metrics were compared to obtain the optimal height statistics in the Z_{om} estimation models. Additionally, we calibrated ALS-derived mean vegetation heights with TLS-derived mean vegetation heights. This was performed to address the possible underestimation of mean vegetation heights from ALS and to assess the effectiveness of ALS-derived mean vegetation height in Z_{om} estimation models. The calibrated heights were also used in the two Z_{om} estimation models to assess whether the calibrated heights improved the estimates. We evaluated the sensitivity of the Z_{om} estimation based on the spatial scale at which height variability is calculated in the MR1994 model. To evaluate the sensitivity of FAI in the RA1994 model, two FAI calculation methods were compared. The workflow is shown in Figure 2.

Vegetation Height Metrics and DEM Derived from Lidar

Figure 2. Workflow diagram.

The TLS data were registered, cleaned (removal of noise points) and height filtered in the RiSCAN Pro software package (Riegl GmbH, Horn, Austria) and BCAL Lidar Tools (Streutker and Glenn, 2006; <http://bcal.boisestate.edu/tools/lidar/>). The ALS data were height filtered with the BCAL Lidar Tools. Both ALS and TLS were height filtered using 5 m and 50 cm canopy spacing, respectively, a 5 cm ground threshold, nearest neighbor interpolation, and 50 iterations (Streutker and Glenn, 2006). We then transformed the height filtered lidar point data to raster products. Eight ($n = 8$) vegetation height metrics (Table 3) were rasterized at seven resolutions (0.5, 1, 3, 5, 10, 15, 30 m) from both the TLS and ALS data. The ALS-derived mean height had up to a 30 percent underestimation of the mean vegetation heights from TLS data, which is in agreement with previous studies in sagebrush-steppe communities from airborne lidar (Streutker and Glenn, 2006; Glenn *et al.*, 2011; Mitchell *et al.*, 2011). Therefore, the ALS-derived mean height was calibrated and scaled with the TLS-derived mean height. The eight ALS-derived raster height-related products and the calibrated mean height were then used in the MR1994 and RA1994 models for Z_{om} calculations. The RA1994 method was conducted at 3 m resolution to match the resolution of imaging spectroscopy data. The MR1994 method used the lidar data only and was tested at varying resolutions (see below). The RA1994 and MR1994 models were compared at 3 m resolution. Correspondingly, a DEM at 3 m resolution from the ALS data was generated for the source area analysis to compare the EC-based Z_{om} with the remote sensing estimated Z_{om} maps.

Table 3. Height Metrics from Lidar Data

Lidar variables	Description
Max	Maximum height
Mean	Mean height
Median(H50)	Median height
H75	The 75th percentile of all lidar vegetation returns within a pixel
H90	The 90th percentile of all lidar vegetation returns within a pixel
H95	The 95th percentiles of all lidar vegetation returns within a pixel
MAD	Median Absolute Deviation (MAD) from median height of all lidar vegetation returns within a pixel. $MAD = 1.4826 * \text{median}(\text{height} - \text{median height})$
AAD	Mean Absolute Deviation (AAD) from mean height of all lidar vegetation returns within a pixel. $AAD = \text{mean}(\text{height} - \text{mean height})$

Estimates of Cover Percentage of Roughness Elements with Lidar and Imaging Spectroscopy Data

In this study, we used random forests (RF) (Breiman, 2001) to obtain the cover percentage (PVC) of the roughness elements (shrub and grass) from hyperspectral and lidar metrics. We then calculated the FAI from PVC for the final Z_{om} estimates. Similarly, previous studies have used spectral and lidar metrics in RF to predict forest canopy structural measurements (Leutner *et al.*, 2012) and percent cover of shrub (Mitchell *et al.*, 2015). We derived variables from the co-registered hyperspectral and ALS data to predict shrub and grass cover by adopting approaches similar to those described in Mitchell *et al.* (2015). The hyperspectral data were atmospherically corrected using HyMap Correction (HyCorr2) and corrected for cross-track illumination. The height filtered lidar data were rasterized to produce vegetation height raster imagery at 3 m. The eight different vegetation height metrics were shown in Table 3. The hyperspectral and lidar imagery are co-registered

by specifying coincident ground control points. A series of vegetation indices ($n = 21$) used in Mitchell *et al.* (2015) were derived from the co-registered hyperspectral. The hyperspectral-derived vegetation indices, the lidar-derived thirty-three ($n = 33$) vegetation metrics (see details in <http://bcal.boisestate.edu/tools/lidar/>), and the additional first twenty ($n = 20$) minimum noise transformed (MNF) bands from the hyperspectral data were evaluated as variables in RF for the calculation of grass and shrub cover. Nearest neighbor imputation was used to generate a spatially explicit raster response surface (Crookston and Finley, 2008) that contains predicted values for the variable of interest (e.g., shrub and grass cover) at unsampled locations.

Z_{om} Estimates with Remote Sensing Data

Z_{om} Estimates Based on Height Variability by Method MR1994

The method MR1994 parameterizes Z_{om} based on height variability using the mean and standard deviation of vegetation height (Menenti and Ritchie, 1994) (Equation 1). Estimations of Z_{om} from the lidar-derived heights were performed for each grid cell by using the variability in roughness heights. Two scale terms, the estimate and slice scales, are used in this method. The estimate scale is the grid cell size (spatial resolution) at which Z_{om} is estimated and the slice scale is the segment size inside the estimate scale (Figure 3). Z_{om} was estimated by Equation 1:

$$z_{om} = \gamma_N \Sigma [\sigma_{h,i} / h_i] * \bar{h} \quad (1)$$

where Z_{om} and $\bar{h}$ are the aerodynamic roughness length estimate and the average roughness element height from lidar at the estimate scale, respectively; N is the number of segments within the grid cell of the estimate scale; $\sigma_{h,i}$ is the standard deviation of the lidar-derived roughness element height in the segment i ; and h_i is the lidar-derived roughness element height in segment i .

Figure 3. Schematic diagram of estimate and slice scales.

Model Sensitivity

A sensitivity analysis was performed to analyze the dependencies of MR1994 on the height and height variability of the roughness elements. We ran eighty-eight ($n = 88$) separate analyses using different slice scales (0.5 m and 1 m) at different estimate scales (1, 3, 5, 10, 15, and 30 m) for the eight different height metrics shown in Table 3.

Z_{om} Estimates Based on Wind Profile by Method RA1994

The method RA1994 is based on the wind profile. The wind velocity profile over the land surface is commonly approximated by a simple logarithmic expression that assumes near neutral buoyancy conditions. The method RA1994 parameterizes Z_{om} by combining vegetation density, height, and wind speed information in Equations 2 and 3. FAI (λ_f) is the ratio of frontal surface (perpendicular to the flow) over the total surface covered by roughness elements and represents the surface roughness density (Grimmond and Oke, 1999; Burian *et al.*, 2002), and is used in both the calculation of d_0 and Z_{om} . Notably, this method accounts for the vegetation density, but not for the distribution of roughness.

$$\frac{d_0}{h_v} = 1 - \frac{1 - \exp\left[-\left(C_{dl} 2 \lambda_f\right)^{0.5}\right]}{\left(C_{dl} 2 \lambda_f\right)^{0.5}} \quad (2)$$

$$\frac{Z_{om}}{h_v} = \left(1 - \frac{d_0}{h_v}\right) \cdot \exp\left(-k \frac{U}{u_*} + \varphi_h\right) \quad (3)$$

with

$$\frac{u_*}{U} = \min\left[\left(C_s + C_R \lambda_f\right)^{0.5}; \left(\frac{u_*}{U}\right)_{\max}\right] \text{ and } \lambda_f = \frac{A_f}{A_T}$$

where d_0 is the displacement height; Z_{om} is the aerodynamic roughness; h_v is vegetation (roughness element) height; u_* is the friction velocity; k is the von Karman constant; U is the wind velocity; φ_h is the roughness-sublayer influence function, describing the departure of the velocity profile just above the roughness from the inertial-sublayer logarithmic law; C_s is the drag coefficient for a roughness element free surface; C_R is the drag coefficient for an isolated roughness element; C_{dl} is a

free parameter; and $\left(\frac{u_*}{U}\right)_{\max}$ is equal to 0.2, as calculated from

the EC data in 05, 06, and 14 August 2010. Recommended values for k , φ_h , C_s , C_R and C_{dl} are 0.41, 0.193, 0.003, 0.3 and 7.5, respectively (Raupach, 1994; Colin *et al.*, 2010).

To solve Equations 2 and 3 for d_0 and Z_{om} , one must calculate λ_f , which is equal to the ratio of the frontal surface area and total surface area. In this study, two methods were tested to calculate λ_f . The first method uses the height and the percentage of the roughness elements for λ_f estimation (F_{cover}). The second method uses the vegetation height differences among different directions and intervals along the wind direction. The intervals are equivalent to the pixel size (F_{section}).

Estimation of λ_f Using the Height and the Percentage of the Roughness Elements (F_{cover})

Calculation of F_{cover} assumes the roughness elements have equivalent average height and trend towards a homogeneous, compact surface. The roughness element was considered either a cuboid (Equation 4) or cylinder shape (Equation 5). λ_f was estimated by the ratio of the frontal surface (A_f) and the total surface area (A_T). Given the height of roughness elements derived from lidar, A_f was obtained by the roughness plane (projected) area (A).

Assuming a cuboid shape of a shrub with width of a , $A = a^2$ and $A_f = ah$; then,

$$\lambda_f = h \sqrt{PVC / A_T} \quad (4)$$

Assuming a cylinder shape of a shrub with radius of width r , $A = \pi r^2$ and $A_f = 2rh$; then,

$$\lambda_f = 2h \sqrt{PVC / \pi A_T} \quad (5)$$

where h is vegetation height and PVC is the percent cover of vegetation. A_T is the total surface area and $A_T = \text{spatial resolution} \times \text{spatial resolution}$. We used 3 m spatial resolution to match the resolution of the hyperspectral data. A is the area that roughness elements cover and $A = PVC \times A_T$.

Estimation of λ_f Using Vegetation Height Differences (F_{section})

In the analysis we calculated λ_f using a method previously adopted by Hiyama *et al.* (1996), De Vries *et al.* (2003) and Weligepolage *et al.* (2012). The method assumes that the land surface is isotropic and λ_f can be defined over a cross-sectional line as follows (Figure 4):

$$\lambda_f = \frac{\sum \Delta y}{\sum \Delta x} \quad (6)$$

where Δy is the positive height difference for each Δx in the cross section. In order to estimate surface features we extracted several cross sections (height at 10 cm intervals) along two different directions (north-south and east-west) from the generated vegetation height model.

Figure 4. Schematic of land surface feature parameters. H is the mean height of roughness elements, L is the mean distance between the tops of roughness elements, and S is the mean roughness element width (De Vries et al., 2003).

Model Sensitivity

We ran six separate analyses using different frontal area index calculations and shapes for shrub and grass elements to determine if the RA1994 method is sensitive to the estimation of the roughness length. These six analyses included: λ_{f1} as the λ_f based on shrub cover assuming the roughness element with a cylinder shape; λ_{f2} as the λ_f based on shrub cover assuming the roughness element with a cuboid shape; λ_{f3} as the λ_f based on total vegetation cover (shrubs and grass) cover assuming the roughness element with a cylinder shape; λ_{f4} as the λ_f based on total vegetation cover (shrubs and grass) cover assuming the roughness element with a cuboid shape; λ_{f5} as the λ_f based on a cross section along a north-south (NS) direction; and λ_{f6} as the λ_f based on a cross section along an east-west (EW) direction.

Estimates with EC Measurements

Estimates with EC Measurements for Different Conditions

Z_{om} calculated from the samples of the EC measurements was used as the reference data and was calculated as:

$$Z_{om} = (z - d_0) / \exp\left(\frac{ku}{u_*} + \psi_m\right) \quad (7)$$

Where, z is the measurement height (m); d_0 is the zero plane displacement height (m); k is the von Karman's constant ($= 0.41$); u is the horizontal wind velocity (m/s) measured by the 3-D sonic anemometers at height z ; u_* is the friction velocity (m/s), and ψ_m is the stability correction for momentum. The stability correction for momentum was computed differently for stable, neutral, and unstable atmospheric conditions as (Zhao et al., 2008):

$$\psi_m = \begin{cases} -5(z - d_0) & \text{(under stable conditions)} \\ 0 & \text{(under neutral conditions)} \\ 2\ln(1+X) + \ln(1+X^2) = 2\arctan(X) + \frac{\pi}{2} - 3\ln 2 & \text{(under unstable conditions)} \end{cases} \quad (8)$$

where, L is the Monin-Obukhov length, and X is a function of the Monin-Obukhov length that is expressed as:

$$X = \left[1 - 16\left(\frac{z - d_0}{L}\right)\right]^{\frac{1}{4}} \quad (9)$$

where $L > 0$ and $L < 0$ indicate stable and unstable conditions, respectively, and large values of $|L|$ indicate near neutral conditions (Equation 8). The Monin-Obukhov length L was calculated using the equation in Ottoni (1992).

From the EC measurement data, sensible heat flux H was calculated from the covariance between vertical wind velocity w and sonic temperature T_s ($w'T'_s$) and then corrected with the WPL corrections (Webb et al., 1980). The friction velocity u_* was computed from:

$$u_* = \sqrt[4]{\overline{w'^2 u'^2} + \overline{w' v'^2}} \quad (10)$$

where, the prime represents the deviation of the instantaneous 20 Hz wind velocities from the mean and the over bar represents mean values over a specific time period (30 minutes in our case). The zero plane displacement height d_0 was estimated from a two-concentric-loop iterative method proposed by Zhao et al. (2008). In addition, site 2 had RM Young 81000 3-D anemometers but no Li-Cor LI-7500 CO₂/H₂O analyzer. Therefore, we were not able to perform the Webb-Pearman-Leuning (WPL) correction for the site 2 data. Thus, the estimates of Z_{om} under different atmospheric conditions was only performed at site 1.

Footprint Analyses for the Source Area Contribution to the Estimation

The area surrounding our sensors was uniform in height and density and relatively flat for hundreds of m to km, such that variations in the contributing area influencing measurements due to windspeed or direction likely caused little or no influence on our fluxes or Z_{om} . Because the flux or Z_{om} at an eddy covariance site is a point measurement representing an upwind flux source area, the micrometeorological method provides a single estimate that is a weighted spatial average over the entire instantaneous source area (the contributing area). Yet the remote sensing data provides an estimate of Z_{om} for each grid cell. Therefore, the footprint analyses for the source area were necessary for a direct comparison of EC and remotely sensed model Z_{om} estimates. A cumulative turbulent source area analysis proposed by Hsieh et al. (2000) was performed. This model creates a point estimate of flux contribution (flux units per m^2) for each pixel in the raster. The total contribution from a pixel is then calculated as the product of the point estimate and pixel area. Once the pixel contribution is calculated, contour lines are created with a list of inputs. The source area is defined by contours of up to 95 percent of the cumulative contribution. The sum of the contours describes the contribution of the measured flux originating from that source. Then, a single Z_{om} was derived by weighting the values in the source area (Hsieh et al., 2000; Jia et al., 2012; Bai et al., 2015), where the weights are the values from the contour lines. An additional method using the average of the estimated Z_{om} for grid cells within a 200 m buffer around the EC sites was also compared.

Results

Comparison of TLS-Derived Height and ALS-Derived Height

As expected, the ALS-derived height was underestimated in comparison to the TLS-derived height (Figure 5). Only mean height was used for the TLS calibration because the mean height provides the (center) tendency of height for vegetation. A scale parameter of 1.3 was used to adjust the ALS mean height. The scaled mean height has an average bias of -0.01 m and RMSE (root-mean-square error) of 0.07 m.

Effects of Different Height Metrics on Estimation by MR1994

For all eight height metrics except the H95 and AAD heights, a 1 m slice scale provided higher values of Z_{0m} than using a 0.5 m slice scale (Figure 6a). Roughness length is stable at different scales for each height metric except the H95 height. The standard deviation of roughness length changes with the estimate scales. The coarser the resolution, the smaller the standard deviation, using 1 m or 0.5 m slice scales (Figure 6b). Although the H90 and H95 heights were higher than non-adjusted mean heights, they cannot be used as representative heights since they resulted in excessively high values of Z_{0m} . The mean, median (H50) and H75 heights led to the best approximation to *in-situ* Z_{0m} from EC data when using a 0.5 slice scale.

Effects of Different Vegetation Density Calculations on Estimation by the RA1994 Method

Shrub cover was estimated with approximately 58 percent of variance explained and a RMSE of 7 percent in the RF regression model (Table 4). Grass cover had similar variance explained though the RMSE was higher (11 percent; Table 4). The percentage of shrub was estimated by MAD, IQR, and Veg_Cov from lidar, and ARI and R2G from imaging spectroscopy. The percentage of grass was estimated by MAD and IQR from lidar and the imaging spectroscopy metrics GNDVI, ARI, PSRI, MNF_SWIR4, and MNF_SWIR8 (see Table 5).

Calculations of FAI (λ_f) based on Equations 4, 5, and 6 are shown in Table 6. The assumed shapes resulted in small differences for FAI. When taking grass cover into account, FAI was higher than when accounting for shrub cover alone.

The calibrated height didn't change the FAI estimates when using the F_{section} for the FAI calculation because the same scale parameter was used to increase the height values which were offset in the height difference (in Equation 6); however, the calibrated height affected the FAI calculation by F_{cover} since another variable (PVC) was used in F_{cover} (Equations 4 and 5). From Table 6, the larger the FAI, the smaller the Z_{0m} ; and the larger the height, the larger the Z_{0m} . The predictors MAD, AAD, and median heights resulted in the closest value of Z_{0m} to the site measurement. The result demonstrates that the relationship between Z_{0m} and FAI was not simply linear. Results also indicate that height metrics influenced Z_{0m} estimates more than the different FAI calculations in RA1994 (Figure 7). We also explored the relationships between Z_{0m} estimates

Table 4. Cover Percentage Estimates with Lidar and Hyperspectral Data by RF Model. R^2 and RMSE in RF Regression Model were Listed Here to Show the Accuracy of Percentage Estimate

Species	Source of predictor variables	Predictor variables selected	R^2	RMSE
Shrub	lidar + hyperspectral	MAD, IQR, Veg_Cov, ARI, R2G	0.58	7.35%
Grass	lidar + hyperspectral	MAD, IQR, GNDVI, ARI, PSRI, MNF_SWIR4, MNF_SWIR8	0.57	11.2%

Figure 5. Comparisons of different height metrics from ALS and TLS data.

Figure 6 (a). The mean and (b) the standard deviation of the estimated Z_{0m} using different slice sizes and estimate scales using the MR1994 method. For example, E3mS50cm uses an estimate scale of 3 m and slice scale of 50 cm. Results for max heights were not shown here because Z_{0m} estimations using max height were overestimated (larger than 0.15 m).

Figure 7 (a) The mean, and (b) the standard deviation of estimated Z_{0m} using RA1994. Results for max height were not shown here because Z_{0m} estimations were overestimated (larger than 0.4 m).

Figure 8. Scatterplots of Z_{0m} with (a) mean height, (b) standard deviation of height, (c) percent shrub cover, and (d) frontal area index (λ_{f3}).

Table 5. Variables in Table 4

Predictor variables	Description
From Lidar	
IQR	Interquartile Range (IQR) of height of all lidar vegetation returns within a pixel IQR = $Q_{75} - Q_{25}$, where Q_{75} and Q_{25} are 75 th percentile and 25 th percentile.
MAD	Same in Table 3
Veg_Cov	Percent ratio of lidar vegetation returns (greater than 0.15 m height) and total returns within a pixel
From Hyperspectral	
ARI	Anthocyanin Reflectance Index (ARI) = $(800 * (1/R_{510}) - (1/R_{700}))$
R2G	Red band and Green band Ratio (R2G) = R_{red} / R_{green}
GNDVI	Green Normalized Difference Vegetation Index (GNDVI) = $(R_{nir} - R_{green}) / (R_{nir} + R_{green})$
PSRI	Plant Senescence Reflectance Index (PSRI) = $(R_{680} - R_{500}) / R_{750}$
MNF_SWIR4	The fourth shortwave infrared (SWIR) band from the SWIR bands after MNF
MNF_SWIR8	The eighth shortwave infrared (SWIR) band from the SWIR bands after MNF

using the two methods with mean height, standard deviation of height, PVC and FAI (λ_p) (Figure 8). In comparison to the MR1994 method, the RA1994 method resulted in a larger range of Z_{om} estimates and has a linear relationship with mean height and FAI.

When MAD was used to represent the roughness element height in RA1994, Z_{om} using shrub cover is very similar to Z_{om} using the total (shrubs + grass) cover with R^2 of 0.99 (Figure 9a). Thus the higher roughness element density due to the grass did not result in a higher Z_{om} in this study. We explored this result by examining the histograms of the grass-dominated pixels (PVC >75 percent) in comparison to the histograms of shrub-dominated pixels (PVC >35 percent) (Figures 9b and 9c). The grass-dominated pixels have a lower mean value of Z_{om} than the shrub pixels due to the lower height of grass, even though grass cover is higher across this landscape.

Table 6. FAI (λ_p) Calculations

FAI types	FAI calculation method		FAI value		FAI value	
	Based on F_{cover}		using mean height		using scaled mean height	
	Vegetation cover	Shape	Mean	Std. Dev.	Mean	Std. Dev.
λ_{f1}	Shrub cover	Cylinder	0.021	0.009	0.028	0.012
λ_{f2}	Shrub cover	Cuboid	0.020	0.008	0.025	0.010
λ_{f3}	Shrub cover + grass cover	Cylinder	0.030	0.011	0.039	0.014
λ_{f4}	Shrub cover + grass cover	Cuboid	0.027	0.009	0.034	0.012
FAI types	FAI calculation method		FAI value		FAI value	
	Based on $F_{section}$		using mean height		using scaled mean height	
	Cross-sections	Direction	Mean	Std. Dev.	Mean	Std. Dev.
λ_{f5}	Based on cross-sections	NS	0.024	0.002	0.024	0.002

Comparison of Remote Sensing Data-Derived and Meteorological Data-Derived

Figure 10 illustrates the cumulative turbulent source area and the 200 m buffer region around the towers in the study area, overlaid by Z_{om} estimates based on the mean height using the RA1994 method. Heterogeneity in vegetation height is limited in this study area and thus calculating Z_{om} as an average across the 200 m buffer had similar results as using the entire study area. Only slight differences were found between Z_{om} estimates in the 200 m buffer and in the cumulative turbulent source area (Table 7). The remote sensing derived Z_{om} values are larger than the multi-year (2 years) EC derived data (Table 7). However, the values are more similar when correlating the Z_{om} calculations from the eddy covariance measurements with the same dates as the remote sensing data collection (05, 06, and 14 August 2010). The remote sensing derived Z_{om} ranges from 0.055 to 0.075 m, with the minimum value closest to near neutral conditions (mean of 0.060 and std. dev. of 0.023 for Z_{om}) (Table 8, Figure 11). Mean Z_{om} varies for neutral conditions (0.060 m), stable conditions (0.048 m), and unstable conditions (0.039 m) (Figure 11). The values of Z_{om} derived from the CSAT EC data with wind speed larger than 3 m/s had good agreement with Z_{om} values from CSAT EC data with all wind speeds at near neutral and unstable conditions (Table 8). Although the Z_{om} values from the remote sensing and RMYoung data are more similar, the smaller values of the CSAT data are expected to be more reliable than those from the RMYoung data (Greth *et al.*, 2013) (Table 7).

Discussion

Variation between the multi-year EC data and remote sensing derived Z_{om} values may be attributed to a number of reasons. For example, the multi-year EC data are averaged over seven years, whereas the remote sensing data observations come from an instantaneous observation at the end of the seven-year period. The variations in Z_{om} highlight the differences in temporal and spatial resolution of the *in situ* and remote sensing data. Using the EC estimates from the time of remote sensing data collection (05, 06, and 14 August 2010) has a better correlation, but does not necessarily account for coarser time-scale variations. The lidar measurements across larger areas are complementary to the EC measurements which can represent Z_{om} across a range of atmospheric conditions.

Figure 9. (a) Scatterplot of Z_{om} using shrub cover and Z_{om} using total (shrubs + grass) cover given mean height for roughness elements; (b) histogram of Z_{om} for pixels with grass cover more than 75 percent (maximum grass cover is 80 percent); (c) histogram of Z_{om} for the pixels in which shrub cover is more than 35 percent (maximum shrub cover is 41 percent). Mean is the average value of Z_{om} . Z_{om} was estimated by RA1994 in all plots.

Table 7. Comparison of Remote Sensing Data Derived Z_{om} (Based on Mean Height and MAD Height) and Multi-Year (2004 to 2010) EC Data Derived Z_{om}

				Z_{om} (m)	Z_{om} (m)
				Using mean height	Using MAD height
Methods based on Remote Sensing					
RA1994: Based on lidar + hyper-spectral	Site 1	Average over the source area		0.072	0.060
	Site 2	Average over the 200 m buffer area		0.069	0.057
		Average over the source area		0.067	0.055
		Average over the 200 m buffer area		0.069	0.057
MR1994: Based on lidar data	Site 1	Average over the source area		0.066	0.075
	Site 1	Average over the 200 m buffer area		0.068	0.077

Table 8. Z_{om} (m) Calculated from CSAT Eddy Covariance Measurements On 05, 06, and 14 August 5, 6 and 14 2010

CSAT data	All wind speed data			Data with wind speed > 3 m/s		
	Mean	Std. Dev.	Number of samples	Mean	Std. Dev.	Number of samples
All atmospheric conditions	0.047	0.044	89	0.050	0.022	56
Near neutral	0.060	0.023	20	0.060	0.023	20
Unstable	0.048	0.025	37	0.047	0.021	32
Stable	0.039	0.065	32	0.029	0.005	4

Note: Number of samples is the half-hourly EC data obtained from the 36,000 sets of 20Hz original EC measurement data. A QA/QC and corrections were performed on the original data resulting in the number of samples represented here.

Figure 10. Z_{om} estimates based on mean height using RA1994. The white outlines the cumulative turbulent source areas and the red circles are the 200 m buffer regions around the towers.

Figure 11. Z_{om} derived from CSAT EC data at different atmospheric conditions. The maximum and minimum values are the range of Z_{om} derived from remote sensing data (see Table 7).

Similar to previous studies (Brown and Hugenholtz, 2012; Paul-Limoges *et al.*, 2013), we found that the method used to calculate the height and standard deviation of height from lidar significantly influenced the Z_{om} estimation in the RA1994 method. However, there are no criteria for choosing a particular segment size or radius filter to make these calculations. In studies by Brown and Hugenholtz (2012) and Paul-Limoges *et al.* (2013), a filtering radius using a moving window was used to account for neighboring pixels for the vegetation height and its standard deviation. This procedure was utilized due to the effect of different filter sizes on the estimation of ground surface elevation from lidar (Wang *et al.*, 2009). However, the filter radius method can also introduce noise generated from the neighboring pixels if they have large differences from the pixel of interest. Therefore, the filter radius method was not utilized in this paper and instead the estimation and slice scales were used to calculate vegetation height and its standard deviation. This approach allows consideration of height variability at the grid cell size of interest. In this paper, the 50 cm slice scale led to smaller and better results than the 1 m slice scale. The variability of height at coarser slice scales demonstrated large height differences in comparison to finer slice scales, where the variability of height can capture the relative variation of a shrub. The slice scale was selected in this study by balancing the point density and individual shrub size.

We also found that different lidar-derived height statistics resulted in differences in Z_{om} estimates and that the arithmetic mean height did not lead to the most accurate estimate of Z_{om} . Mean height, median height, and H75 height resulted in better Z_{om} estimates than other height metrics in the MR1994 model and median height resulted in the closest Z_{om} value in comparison to the EC-derived Z_{om} . However, mean, median, MAD, and AAD heights had better Z_{om} estimation than other height metrics in the RA1994 model. Similar to Mitchell *et al.* (2015), MAD height proved to be a robust metric that captures the variability of the shrub height and resulted in Z_{om} estimates closest to the EC-derived Z_{om} .

We assumed a limited amount of sagebrush growth from the one to two-year time gap between ALS and TLS data acquisitions (Zeng *et al.*, 2008). However, a single scaling parameter did not account for variations in the differences between ALS and TLS mean heights among the pixels. Although the scaling parameter increased the magnitude of aerodynamic roughness, the results showed that the scaled height led to a larger bias than the un-scaled mean height when compared to the *in-situ* Z_{om} . Interestingly, both AAD and MAD, which capture the variability of height, had similar results in the RA1994 method (Figure 6) and provided the best estimates. We interpret that height variation rather than mean height serves an important role for calculating aerodynamic roughness, emphasizing the need to capture height variability across space with remote sensing. In contrast, in the MR1994 method the un-scaled mean height resulted in the aerodynamic roughness most approximate to the *in-situ* EC measurements. Compared to the RA1994 model, the MR1994 can be implemented more easily with only height-related information in a relatively homogenous area. However, in complex and heterogeneous areas where the frontal area index can be obtained, the RA1994 method may be more representative of Z_{om} . Although more driving parameters are needed for the RA1994 model, the sensitivity of these coefficients should be tested for different ecosystems. Additionally, a more accurate method would be to use higher density airborne lidar observations (>8 points per m^2) to potentially capture more accurate height variability. We used a 3 m spatial resolution for our analysis because this was the pixel size of the imaging spectroscopy data. A finer-scale pixel size could be used

with lidar data of sufficient point density. However, sub-pixel analysis of the imaging spectroscopy data in this low vegetation cover ecosystem is challenging. In addition, because we used narrow-band indices for our spectroscopy analysis, a finer pixel-scale analysis will require collecting data at higher spatial resolution.

In addition to height, aerodynamic roughness varied along density, spatial pattern and geometry of roughness elements. However, we found that the Z_{om} estimation using shrub cover had only small differences from that using total percent roughness element cover (shrub and grass cover). This may be due to the ALS mean height only capturing shrubs, as grass heights are within the vertical error of this small footprint lidar. Another reason that the grass had a low impact on the Z_{om} in our study area may be due to its low height, and thus lower resistance. Although the grass was accounted for in the frontal area index calculation, the ratio of the friction

velocity and the wind velocity $\left(\frac{u_*}{U}\right)$ limited the increase of

Z_{om} due to the increase of the cover percentage of roughness elements. Our results indicate that in this mixed shrub-grass community, the shrub component contributed the most resistance of roughness elements for wind and thus when using the cover percentage for the frontal area index estimates, grass cover is not necessary to include. The combination of lidar and hyperspectral data improved the vegetation percent cover estimates but had less improvement for shrub in comparison to grass (Mitchell *et al.*, 2015; Glenn *et al.*, 2016). Thus, in areas where imaging spectroscopy data cannot be obtained, especially where grass is sparse, lidar can be sufficiently used alone for shrub cover estimates and for frontal area index estimates of aerodynamic roughness.

In the RA1994 method, the roughness element density was equal to the percent vegetation cover in magnitude. However, the pattern of roughness elements cannot be interpreted from percent vegetation cover. In addition, the porosity of the vertical vegetation structure was not considered. Uncertainty was also introduced into the Z_{om} estimates by using simplified cuboid and cylinder shapes to represent shrubs and the assumption of compaction of roughness elements. Further exploration on the shape and pattern of the roughness elements could be achieved by using finer-scale lidar data (higher point density and full-waveform) or a simulation approach to characterize both the vertical and horizontal structure of the canopy. More accurate percent vegetation cover could also enhance the frontal area index calculation and thus the aerodynamic roughness estimates.

Conclusions

Our study found that the roughness element height information from lidar can be used to map Z_{om} across space. The RA1994 model represented the *in-situ* EC measurements better than the MR 1994 method, and is also more applicable in complex landscapes with varying geometry (e.g., grass, shrub, trees) when assessing the effects of different roughness elements on Z_{om} . While we used imaging spectroscopy data to assist in deriving vegetation cover, we found that grass cover had a small effect on the overall Z_{om} and can be excluded in Z_{om} calculations in this shrub-dominated area. Thus, modeling the shrub component is likely of more importance in similar ecosystems. Further, higher point density lidar (>8 points per m^2) could be used to estimate percent vegetation cover of shrub (Li *et al.*, 2015) and thus reduce the dependency on imaging spectroscopy data in the RA1994 method. Conversely in areas where the vegetation cover is more heterogeneous, imaging spectroscopy data will assist with percent vegetation

cover estimates (Kokaly *et al.*, 2007), and thus contribute a more significant role. We will have additional opportunities to test and apply the RA1994 model to a range of ecosystems over time and space with the increasing availability of lidar data. Resultantly, land surface models will need to accommodate and test the refinement of Z_{om} estimates with remote sensing data. While regional availability of ALS is steadily increasing, two upcoming NASA missions, ICESat-2 (satellite) and GEDI (International Space Station), will provide photon counting and full-waveform datasets, respectively, across broader geographic regions albeit at coarser scales. The data from these missions will provide new opportunities to estimate Z_{om} across time and space.
