(Received 6 June 2018; accepted 18 September 2018; published online 17 October 2018)

In this paper, the magnetic and electrocatalytic properties of hydrothermally grown transition metal doped (10% of Co, Ni, Fe, and Mn) 2H-MoS$_2$ nanocrystals (NCs) with a particle size 25–30 nm are reported. The pristine 2H-MoS$_2$ NCs showed a mixture of canted anti-ferromagnetic and ferromagnetic behavior. While Co, Ni, and Fe doped MoS$_2$ NCs revealed room temperature ferromagnetism, Mn doped MoS$_2$ NCs showed room temperature paramagnetism, predominantly. The ground state of all the materials is found to be canted-antiferromagnetic phase. To study electrocatalytic performance for hydrogen evolution reaction, polarization curves were measured for undoped and the doped MoS$_2$ NCs. At the overpotential of $\eta = -300$ mV, the current densities, listed from greatest to least, are FeMoS$_2$, CoMoS$_2$, MoS$_2$, NiMoS$_2$, and MnMoS$_2$, and the order of catalytic activity found from Tafel slopes is CoMoS$_2$ > MoS$_2$ > NiMoS$_2$ > FeMoS$_2$ > MnMoS$_2$. The increasing number of catalytically active sites in Co doped MoS$_2$ NCs might be responsible for their superior electrocatalytic activity. The present results show that the magnetic order-disorder behavior and catalytic activity can be modulated by choosing the suitable dopants in NCs of 2D materials. I. INTRODUCTION

Two-dimensional (2D) transition metal dichalcogenides (TMDs) are a class of materials with the formula MX$_2$, where M is a transition metal element (Mo, W, etc.) and X is a chalcogen (S, Se, or Te). 2D TMDs form layered structures in the form X–M–X, with the chalcogen atoms in two hexagonal planes separated by a plane of metal atoms. The layer-dependent properties of nanoscale TMDs have recently attracted a great deal of attention due to their extraordinary electrocatalytic, biomedical, and optoelectronic properties.$^{1–10}$ Unlike other 2D materials, such as graphene, these materials are semiconductors with tunable (1.3–1.8 eV) band gaps.

Recent observation$^{11–13}$ of intrinsic 2D ferromagnetism in monolayer van der Waals crystals such as CrI$_3$, Cr$_2$Ge$_2$Te$_6$, and VS$_2$ has invigorated the field of low-dimensional magnetism in layered compounds. The above 2D materials intrinsically contain magnetic elements such as Cr and V, which give rise to ferromagnetic behavior. In particular, there have been numerous theoretical works that have appeared$^{14–30}$ in realizing the dilute 2D semiconducting materials for next generation spintronic materials, which do not contain magnetic elements intrinsically, followed by promising experimental observations.$^{31–37}$ For instance, Yan et al. have shown$^{32}$ that upon Li intercalation the crystal structure transformed from 2H to 1T phase and the magnetism was significantly enhanced from diamagnetism to paramagnetism in 2H-MoS$_2$ nanostructures. With further annealing in argon atmosphere the 2H phase recovered gradually from 1T phase and the magnetism decreased correspondingly, attributed to the Mo atoms of 1T-MoS$_2$. In another work,$^{31}$ freestanding MoS$_2$ nanosheets reveal the clear room-temperature ferromagnetism for all the MoS$_2$ nanosheets. Furthermore, results indicate that the saturation magnetization of the nanosheets increase as the size decreases, attributed to the presence of edge spins on the edges of the nanosheets. Cao et al. have shown$^{33}$ vacancy induced ferromagnetism in MoS$_2$ nanosheets. Huo et al. reported$^{36}$ that multilayer WS$_2$ nanosheets exhibit strong ferromagnetic behavior with saturation magnetization (M$_s$) of 0.0058 emu/g and coercive field (H$_C$) of 92 Oe at room temperature, attributed to the zigzag edge sulfur and tungsten atoms. In addition, a few more reports have recently appeared$^{34–37}$ on the magnetic properties of TMD nanostructures upon doping with Co, and Mn prepared through the hydrothermal method. However, to date, the experimental studies on the magnetic properties of TMD nanostructures are limited. Most of the prior works focused on the magnetic properties mainly at the low (<5%) doping level, and the relevance to their catalytic activity is not studied. To broaden the current knowledge and understanding on the doping induced magnetic properties, a comprehensive experimental study is required—that forms the first part of this study.

TMD NCs are also known to show excellent catalytic properties.$^{38–44}$ For instance, MoS$_2$ is a potential hydrogen...
evolution material for clean energy applications. The evolution of hydrogen from water has allured the scientific community for the possibility of using hydrogen as a clean energy source. In the process of extracting hydrogen from water via hydrogen evolution reaction (HER), studies have shown that Pt electrodes possess the best electrocatalytic properties. If it were not for the rarity of this element, the pursuit of other materials for the reaction would not be necessary. It is therefore in the best interest of the scientific community to find earth-abundant materials that can be used in place of Pt. One such earth-abundant material is MoS2, which, in its bulk form, has been suggested for use as a catalyst in the evolution of hydrogen. MoS2 was originally studied as a catalyst for hydrodesulfurization. It has been shown that the electrocatalytic performance of MoS2 can be improved when it is prepared in the nanocrystalline form due to the formation of increasing number of active edge sites by doping with transition metals, in the same way as was done for hydrodesulfurization. In the second part of this paper, the catalytic properties of the transition metal (Co, Ni, Fe, and Mn) doped (10%) MoS2 NCs were studied.

Together, in this work, transition metal (Co, Ni, Fe, Mn) (10%) doped MoS2 NCs were prepared and their magnetic and catalytic properties were studied. In particular, it has been shown that it is possible to induce room temperature weak ferromagnetism in Co, Ni, and Fe doped MoS2 NCs, while Mn doped MoS2 NCs showed paramagnetic-like behavior at room temperature. Furthermore, the catalytic performance of doped materials is compared with respect to that of pure MoS2 NCs. This study forms a significant step forward to introduce new opportunities for fully exploiting these materials for advanced spintronic and catalytic applications.

II. EXPERIMENTAL DETAILS

MoS2 NCs were synthesized by using a most common facile bottom-up “hydrothermal method”. Unlike other “top-down” approaches (chemical exfoliation, sonication of bulk MoS2, electro-Fenton processing, etc.), this route eliminates harsh synthesis conditions, excludes hazardous chemicals, and is faster. Hydrothermal method has been routinely employed in preparing the nanostructures of transition metal (Co, Cu, V, Mn) doped MoS2 up to the doping level of 16%. Previously, this method was successfully employed by some of us (Singamaneni and Gandha) in preparing nanocrystalline magnetic nanowires. To describe the procedure briefly, 0.4 g of Na2MoO4·2H2O was dissolved in 30 ml distilled water under sonication for 20 min. At this step, the desired metal precursor is added. 0.38 g of dibenzyl disulfide was then added to the solution along with 30 mL of ethanol and sonicated for 30 min. The solution was then transferred into a 100 ml Teflon-lined stainless-steel autoclave and was maintained at 250 °C for 18 h. After 18 h, the reaction system was allowed to cool down to ambient temperature. The obtained products were collected by centrifugation and washed with deionized water. The stoichiometric MoS2 NCs were filtered and left to dry over night at room temperature in vacuum. Using this approach, 10% Co, Ni, Fe, and Mn doped MoS2 NCs were prepared. All the precursors were purchased from Alfa Aeser and used without further purification. The magnetization measurements were performed using Quantum Design PPMS (5–300 K, ±5 T). Electron spin resonance (ESR) data were recorded on a Bruker EMX Plus X-band (~9.40 GHz) ESR spectrometer, equipped with a high sensitivity probe head. A ColdEdge™ ER 4112HV In-Cavity Cryo-Free VT system connected with an Oxford temperature controller was used for low temperature measurements. The complete system was operated by Bruker Xenon software. Additionally, all ESR experimental settings were kept constant for reproducibility. For all ESR measurements, the sample was wrapped in a Teflon tape, and inserted into a quartz tube. During the magnetic measurements, all the samples were carefully handled with nonmagnetic capsules and tapes to avoid contamination. X-ray diffraction (XRD), transmission electron microscopy (TEM), Raman spectroscopy, and X-ray photo absorption spectroscopy (XPS) measurements were employed to study the crystallinity, phase formation, doping effects, and valence states of elements before and after doping with transition metal elements (data not shown).

All catalysts were accessed heterogeneously for hydrogen production. Prior to electrochemical studies, the catalysts were deposited on a conductive fluorinated-tin oxide (FTO) substrate with a conductive adhesive silver paste to better support the catalyst. FTO glass was cleaned by being sonicated in acetone, isopropyl alcohol, and deionized water separately. The silver paste was then coated on top of the active side of the FTO with an area of 0.25 cm² (0.5 cm × 0.5 cm). 0.5 mg of the catalyst was dispersed in 1 ml ethanol and sonicated for 30 min to form a homogeneous ink. 10 μl of the catalyst ink was then drop cast on the silver paste and the plate was allowed to dry in ambiance, which was later used as the working electrode for electrochemical measurements. All electrochemical studies were performed on a CHI760D potentiostat with a three-electrode electrochemical cell in room temperature. A platinum wire was utilized as the counter electrode while a saturated calomel electrode (SCE) was used as the reference electrode. All potentials displayed in this work were referred to reversible hydrogen electrode (RHE) by adding a value of (0.245 + 0.059 pH) to the data obtained using a SCE reference electrode. An aqueous solution of 0.5M H2SO4 was used as both the proton source and electrolyte. The solution was saturated with nitrogen gas to remove the dissolved oxygen prior to each measurement. Electrical impedance spectroscopy (EIS) was obtained at different overpotentials from 100 KHz to 0.1 Hz with AC voltage of 5 mV.

III. RESULTS AND DISCUSSION

A. Magnetic properties

1. MoS2 NCs

To study the magnetic properties of MoS2 NCs, temperature- and magnetic field-dependent magnetization
measurements were performed. In Fig. 1(a), the temperature dependence of susceptibility ($\chi$) is plotted. $\chi$ was measured from 10 to 300 K, after a $\mu_0 H = 1$ T magnetic field cooling. As it can be noticed, $\chi$ increased with cooling. A similar observation was reported on many other materials\textsuperscript{31,32,37,62} such as exfoliated WS\textsubscript{2} nanosheets, graphene nanoribbons, Li intercalated MoS\textsubscript{2} nanosheets, and amorphous MoS\textsubscript{2}.

To better understand the observed magnetic behavior, the $\chi$-$T$ curve was fitted using modified Curie-Weiss (CW) model\textsuperscript{32} $$\chi = \chi_{dm} + C/(T+\theta),$$ which involves the diamagnetic and paramagnetic contributions. Here, $\chi_{dm}$ is the diamagnetic susceptibility, $C$ = Curie constant, $\theta$ = CW temperature, and $T$ = measurement temperature. The fitting results (blue) are shown in Fig. 1(a) along with the experimental data (black). Both the diamagnetic and paramagnetic components were resolved. In addition, the fitting results are tabulated in Table I. The value of $\theta$ was obtained as 3 K for the MoS\textsubscript{2} NCs. As shown in Table I, the value of $\theta$ is positive indicating antiferromagnetic behavior,\textsuperscript{32} which, however, is associated with uncompensated spins that result in finite magnetization. That is the typical signature of canted antiferromagnetic phase. Negative $\theta$ values would indicate ferromagnetism.

Now, attention will be turned to the magnetic field-dependent magnetization behavior. Isothermal magnetization as a function of magnetic field was measured between 10 and 300 K. The data are plotted in Figs. 1(b)–1(f). At 10 K, observation of a nearly anhysteretic behavior with a positive slope indicates canted antiferromagnetic phase. As temperature increases further, a more magnetic hysteretic behavior was observed at low fields but the anhysteretic behavior persists at higher fields. These features together with $\chi$-$T$ variation [Fig. 1(a)] indicate that MoS\textsubscript{2} NCs showed a canted antiferromagnetism at low temperature and weak ferromagnetism at room temperature. It was verified that the modified

\begin{table}[h]
\centering
\begin{tabular}{|c|c|c|c|}
\hline
Sample & C & $\Theta$ (K) & $\chi_{dm}$ \\
\hline
Undoped MoS\textsubscript{2} NCs & $4.767 \times 10^{-3}$ & 3.406 & $-9.454 \times 10^{-17}$ \\
Fe doped MoS\textsubscript{2} NCs & $4.257 \times 10^{-3}$ & 3.296 & $-3.732 \times 10^{-17}$ \\
Ni doped MoS\textsubscript{2} NCs & $5.396 \times 10^{-3}$ & 3.173 & $-6.123 \times 10^{-17}$ \\
Co doped MoS\textsubscript{2} NCs & $9.895 \times 10^{-3}$ & 2.935 & $1.883 \times 10^{-16}$ \\
Mn doped MoS\textsubscript{2} NCs & $3.756 \times 10^{-3}$ & 2.841 & $-5.526 \times 10^{-16}$ \\
\hline
\end{tabular}
\caption{The parameters obtained from the modified Curie-Weiss (CW) fits of all the samples studied here.}
\end{table}
Brillouin function \(^{32}\) (see below) could not account for the room temperature M-H behavior.

\[
M = X_d H + M_s \left[ \frac{2J + 1}{2J} \coth \left( \frac{2J + 1}{2J} X \right) - \frac{1}{2J} \coth \left( \frac{X}{2J} \right) \right].
\]

This function consists of a linearly field-dependent function, which represents diamagnetism added with the classic Brillouin function, which refers to paramagnetism. In the above equation, the variable \(M_s\) is the saturated magnetization, \(M_s = N g \mu J\), where \(N\) is the density of spins, \(\mu\) is Bohr’s magneton, \(g\) is the Landé g-factor, and \(J\) is the angular momentum number. The variable \(X\) is equaled to \(gJ \mu H / kT\), where \(k\) is Boltzmann’s constant, and \(T\) is temperature. Fits for the data that were accumulated were obtained by using the modified Brillouin function; however, the numerical values of temperature in these fits did not correlate with what was seen in experimentation, verifying that the modified function could not account for the magnetic-field-dependent magnetization data that were observed at room temperature. A strong hysteretic behavior at 300 K, rather than at 10 K, was noticed. This observation is also reflected in the temperature-dependent coercive field (\(H_c\)) trend plotted in Fig. 2. It is also noticed that \(H_c\) increased from 373 to 880 Oe as the temperature increased from 10 to 300 K. This infers that the ferromagnetism observed at room temperature is of short-range.

To corroborate the magnetic data, the temperature-dependent (50–300 K) resistance measurements (data not...
shown) were performed on all the materials studied here, including undoped MoS$_2$ NCs. The data showed semiconducting behavior (resistance increases as the sample is cooled), consistent with the literature reports, and revealed very little (<0.5%) magnetic field dependence of resistance even upon the application of 3 T magnetic field. These observations are the typical signatures of canted antiferromagnetism.

To provide additional information on the presence of magnetic moments, in our previous work, using X-band (∼9.43 GHz) ESR spectroscopy performed on MoS$_2$ NCs, our group has reported several electron spin centers such as oxygen species, sulfur vacancies, thio-, and oxo-Mo$^{5+}$. It is believed that the exchange interaction among these magnetic species could lead to the observed magnetic phases. These measurements coupled with the data obtained from XPS and Raman spectroscopy showed no indication of unwanted extrinsic impurities that could account for the magnetic behavior observed in the present work.

2. Co doped MoS$_2$ NCs

The temperature-dependent magnetic susceptibility ($\chi$) data were obtained after the sample was cooled to 10 K in $\mu_0H = 1$ T magnetic field [see Fig. 3(a)]. The magnetization value (0.8 emu/g) observed in the present study is higher than those (0.006 to 0.3 emu/g) reported in the literature on similar systems such as Co, Cu, and V doped (<7% doping) MoS$_2$ nanostructures prepared through hydrothermal method. As displayed in Fig. 3(a), the temperature dependence of magnetic susceptibility can be well described by the modified CW model. A positive $\theta$ of 3 K (see Table 1) was obtained, which indicates that the material is antiferromagnetic below the temperature of 3 K.

Isothermal magnetization measurements were performed on Co doped MoS$_2$ NCs by sweeping the magnetic field from −2 to +2 T at 10, 50, 100, 200, and 300 K. The data are presented in Figs. 3(b)–3(e). At 10 K, magnetization shows anhysteretic behavior with the magnetic field with the positive slope, which indicates the (canted) antiferromagnetic behavior. Interestingly, with further increase in temperature, a more hysteretic behavior with coercive field of 400 Oe becomes pronounced, suggesting unambiguous room-temperature ferromagnetism, as evidenced from the s-shaped hysteresis loop. In addition, the applicability of the Brillouin function was tested, and found that it could not account for the magnetic-field-dependent magnetization data observed at

![Graphs showing temperature-dependent magnetic susceptibility and coercivity for different temperatures](image)
room temperature. The saturation magnetization (magnetization at the maximum applied magnetic field) decreases as the measurement temperature increases from 10 to 300 K. This trend is consistent with the temperature-dependent magnetic susceptibility data as shown in Fig. 3(a). Xiang et al. have also reported35 room temperature ferromagnetism from Co doped (<7%) MoS2 nanosheets.

XRD patterns (data not shown) obtained on the samples studied here are identical to the ones reported on the best samples prepared through hydrothermal method in the literature,31,35,37,64 thus confirming that there is no or minimal segregation/clustering of dopants. If there is a significant clustering effect, one would expect to observe high ferromagnetic TC much beyond room temperature,65 which is clearly not the case here.

3. Ni doped MoS2 NCs

Temperature-dependent magnetic susceptibility data was collected after the sample was field cooled at $\mu_0H = 1$ T magnetic field [Fig. 4(a)]. The magnetization value (0.4 emu/g) observed in the present study is comparable to those reported in the literature on similar systems.35,37,54,55 The modified CW model as depicted in Fig. 4(a) can describe the temperature-dependent magnetization behavior. The obtained $\theta$ is 3 K (see Table I), suggesting that the material is antiferromagnetic below 3 K.

The isothermal magnetization measurements were performed on Ni doped MoS2 NCs by sweeping the magnetic field from −2 to +2 T at 10, 50, 10, 200, and 300 K. The data are presented in Figs. 4(b)–4(e). At 10 K, magnetization anhysteretic behavior as a function of magnetic field was observed, which indicates (canted) antiferromagnetic behavior. Interestingly, as temperature is increased further, a hysteretic behavior with coercive field of 175 Oe appears, suggesting unambiguous room-temperature ferromagnetism. The saturation magnetization decreases as the measurement temperature increased from 10–300 K. This trend is consistent with the temperature-dependent magnetic susceptibility data shown in Fig. 4(a). Similar to the case of Co doped MoS2 NCs, Brillouin function could not account for the magnetic-field-dependent magnetization data observed at room temperature. To our knowledge, with the exception of one report66 on the catalytic behavior of Ni doped MoS2 nanoparticles, there have been no previous works reporting on the magnetic properties of Ni doped MoS2 NCs to compare these data at any doping percentage.

4. Fe doped MoS2 NCs

Like the measurements performed on Co and Ni doped MoS2 NCs, magnetization data were collected on Fe doped MoS2 NCs. The temperature-dependent magnetic susceptibility

![Graph showing temperature-dependent magnetic susceptibility and magnetic field-dependent magnetic behavior of Fe doped (10%) MoS2 NCs.](image-url)
data were recorded after the sample was cooled in $\mu_0H = 1$ T magnetic field [see Fig. 5(a)]. The magnetization value (0.3 emu/g) obtained in the present study from the $\chi$-T curve is comparable to that (0.25 emu/g) reported in the literature on 1.74% Fe doping in MoS$_2$ nanostructures.\textsuperscript{64} As displayed in Fig. 5(a), it was found that the modified CW model describes well the temperature-dependent magnetic susceptibility behavior. From the fits, the $\theta$ is obtained as 3 K (see Table I), which indicates that the material is antiferromagnetic below 3 K.

The isothermal magnetization data are presented in Figs. 5(b)–5(e). At 10 K, similar to the previous samples, magnetization shows anhysteretic behavior with the magnetic field, which indicates (canted) antiferromagnetic behavior. However, at 300 K, the M-H behavior of this material shows a combination of ferromagnetic (at low fields) and antiferromagnetic behavior (at high fields). This is in sharp contrast with the Co and Ni doped samples, which show complete ferromagnetic behavior at room temperature. The saturation magnetization decreases as the measurement temperature increased from 10 to 300 K. This trend is consistent with the temperature-dependent magnetic susceptibility data shown in Fig. 5(a). In addition, it has been verified that Brillouin

function could not account for the magnetic-field dependent magnetization data observed at 300 K. Xia et al. also reported\textsuperscript{64} room temperature ferromagnetism in Fe doped (<3.18%) MoS$_2$ nanosheets prepared through hydrothermal process. The interaction between the sulfur vacancies and the dopants is argued to be at play. A similar situation may be expected to happen in the present case as well.

5. Mn doped MoS$_2$ NCs

Temperature-dependent magnetic susceptibility and magnetic field-dependent magnetization measurements were performed on Mn doped MoS$_2$ NCs. As shown in Fig. 6(a), the magnetic susceptibility increased as the sample temperature is lowered from 300 K to 10 K. More importantly, it was noticed that the magnetization (measured at 10 K, 1 T) is about 6 times higher than that of pure MoS$_2$ NCs [see Fig. 1(a)]. This observation is the direct effect of doping with Mn. To gain additional insights into the magnetism, the $\chi$-T curve was fitted to the modified CW model comprising both diamagnetic and paramagnetic contributions. The highest Curie constant of $4 \times 10^{-3}$ obtained from the $\chi$-T curve fitting signifies the larger magnetization in comparison to the

FIG. 6. The temperature-dependent magnetic susceptibility and magnetic field-dependent magnetic behavior of Mn doped (10%) MoS$_2$ NCs. Fig. 6(a) also shows the applicability of the modified Curie-Weiss model.
materials discussed above. The fitting results are shown in Fig. 6(a) along with the experimental data. Using this model, the diamagnetic and paramagnetic components were resolved and the CW constant ($\theta$) as 3 K (see Table I) was obtained, which indicates that the material is antiferromagnetic below 3 K. However, a much weaker ferromagnetism was observed at 300 K as reflected by the hysteretic behavior at low fields, and a predominant paramagnetic nature was observed at higher fields. A similar weak ferromagnetism was previously reported for Mn doped SnSe alloys prepared via molecular beam epitaxy methods. Wang et al. reported room temperature ferromagnetism in Mn doped (7%) MoS$_2$ NCs. Park et al. have reported a similar room temperature ferromagnetism from MoS$_2$ NCs upon doping with MoO$_2$ by electrochemical method, associated with the saturation magnetization of 0.02 emu/g. This work not only shows that magnetic properties strongly depend on the nature of the dopant but also the magnetic order-disorder transition varies with dopant type such that Co and Ni doping produces stronger ferromagnetic behavior than Fe and Mn at least at 300 K.

B. Electrocatalytic properties

It has been shown that the electrocatalytic performance of MoS$_2$ NCs can be engineered by doping the active edge sites with transition metals. To study the HER performance, polarization curves (see Fig. 7) were obtained for pristine MoS$_2$ NCs as well as the doped samples. At an overpotential ($\eta$) of 300 mV, the current densities for MoS$_2$, CoMoS$_2$, NiMoS$_2$, FeMoS$_2$, and MnMoS$_2$ were found to be 2.09, 3.00, 1.5, 4.05 mA/cm$^2$, and 52 $\mu$A/cm$^2$. Listed from greatest to least for comparison, the reaction kinetics are as follows: FeMoS$_2$ > CoMoS$_2$ > MoS$_2$ > NiMoS$_2$ > MnMoS$_2$; this was observed to be true for $-372.8$ mV $\leq \eta \leq -169.6$ mV. This progression is the exact same order of activity that was previously found by calculating the hydrogen absorption free energy ($\Delta G_H$). Wang et al. and other groups have doped different transition metals to MoS$_2$ nanostructures, similar to the metals used in the experiments presented here and observed current densities that are comparable with data collected for this study. The onset potential for the MoS$_2$ NCs presented here was 141 mV; this is comparable to the work done by Ren. Thus, the present observations are consistent with the literature reports.

For the HER, the Tafel slope and exchange current density can provide information about the reaction mechanism and kinetics of the process. The Tafel slopes also indicate the rate-limiting step in the HER. Essentially, the lower the Tafel slope, the faster the reaction takes place, and the faster hydrogen is produced. Doping with different transition metals showed a slight change in the Tafel slope, which is consistent with other literature reports. EIS was performed on the samples at overpotentials of 0.445, 0.5, 0.545, and 0.645 V. Figure 8 shows the EIS measurements taken at $\eta = 0.5$ V. Smaller semicircle diameters correspond to higher charge transfer, higher conductivity, and thus lower charge transfer resistance ($R_{ct}$). The samples can be ranked in the order from least to greatest $R_{ct}$ in the following order: Fe, Co, pristine MoS$_2$, Ni, Mn. Fe doped MoS$_2$ NCs have the greatest conductivity and charge transfer ability, while Mn doped MoS$_2$ NCs have the least. Another literature report performed a similar electrocatalytic study of TM-doped MoS$_2$ and found the exact same progression, with $R_{ct}$ increasing from Fe to Ni doping in the same order. This study [Fig. 8(b)] of Mn doped MoS$_2$ showed poor HER performance.

The electrocatalytic performance of CoMoS$_2$ NCs was examined using chronoamperometry to determine the long-term stability of the NCs. The chronoamperometric studies were operated in a custom-built two-compartment gas-tight
electrochemical cell under an argon atmosphere. One of the compartments of the cell contains the working electrode and the reference electrode while the other compartment contains the counter electrode. The solution (0.5M H2SO4 in water) was saturated with argon gas prior to the measurement and the solution on the side of the cell containing the working electrode was kept stirring to remove the in situ generated hydrogen gas. The experiment was conducted with an initial current density of 10 mA/cm2 along with a constant overpotential of \( \eta = 850 \text{ mV} \). The current density was observed to stabilize after approximately 5 h. Even after over 23 h of operation, the CoMoS2 NCs were seen to be electrocatalytically active. Thus, the stability of the nanocrystals has been demonstrated through pragmatic means.

Interestingly, the electrochemical behavior shown in this work is in agreement with what is known in the literature.69,74,75 As noted above, the electrocatalytic activity, from greatest to least is: FeMoS2 > CoMoS2 > MoS2 > NiMoS2 > MnMoS2, which is consistent with previous works.69,74,75 Since the adsorbed atomic hydrogen Gibbs free energy \( \Delta G_H \) is the key to the HER electrocatalytic activity of a catalyst, \( \Delta G_H \) closer to zero corresponds to higher activity. Incorporation of transition metals to MoS2 does not affect the \( \Delta G_H \) of the Mo-edge, but lowers the \( \Delta G_H \) of S-edge, which makes the catalytic inert S-edge catalytically active. Previous studies69,74,75 have shown similar effects when doping with Fe and Co, leading to \( \Delta G_H \) value closer to zero in the S-edge of MoS2, which explains why these two catalysts exhibit the best efficiency.

Now, why the variations in the magnetic and catalytic properties occur as a function of transition metal doping is discussed. The present work, as well as earlier reports66–79 showed that the transition metal elements show interesting magnetic properties as well as pronounced catalytic activity. From the current observations, it is learned that the Mn doped MoS2 NCs showed least catalytic performance and showed predominant paramagnetism at room temperature. Whereas the pristine MoS2 and Co, Ni, and Fe doped MoS2 NCs showed good catalytic performance, as well as stronger room temperature ferromagnetism. To better understand the relationship between the magnetism and catalytic performance, X-band ESR measurements were performed on all the samples at room temperature (300 K). The data are presented in Fig. 9. As it can be clearly noticed, Mn doped MoS2 NCs did not show signals coming from the catalytically active centers, except the strong signal that comes from Mn\(^{2+}\) only. On the other hand, the samples doped with Co, and Ni, including undoped MoS2 NCs, showed many sharp ESR signals, indicating the presence of larger number of catalytically active centers. Hence, it is believed that Co doped MoS2 NCs showed superior catalytic performance compared to Mn doped MoS2 NCs. These active defect centers contain unpaired electron spins due to uncoordinated and dangling bonds. The observed ferromagnetic behavior could have resulted from the interaction between these active spin centers.

Furthermore, the morphology of 10% Co doped MoS2 NCs is distinctly different from that of 10% Mn doped MoS2 NCs, as reflected from the TEM bright field images displayed in Fig. 10. The Co doped sample shows a flowery morphology with randomly oriented sheets of MoS2 that are only a few monolayers thick as indicated by the selected area diffraction (SAED) pattern shown as the inset of Fig. 10(a). On the other hand, the Mn doped MoS2 showed a mixed morphology with some flowery structures, but also mixed with many faceted plates of well crystallized MoS2 that are several hundred nanometers wide and the corresponding SAED pattern is shown as the inset of Fig. 10(b). The [111] zone axis SAED pattern indicates single crystalline nature of these plates with six fold symmetry. One would expect the flowery morphology of Co doped samples to have more surface area compared to the Mn doped samples, which would explain the high catalytic activity of these samples.
IV. CONCLUSIONS

To conclude, the magnetic and catalytic properties of hydrothermally grown transition metal doped (10% of Co, Ni, Fe, and Mn) MoS2 NCs associated with a particle size of 25–30 nm have been reported. Interestingly, the undoped MoS2 NCs showed a mixture of canting anti-ferromagnetic and ferromagnetic behavior. MoS2 NCs doped with Co, Ni, and Fe exhibited profound room temperature ferromagnetism. On the other hand, Mn doped MoS2 NCs showed room temperature paramagnetic nature, predominantly. For all the materials, modified CW law described the temperature dependent magnetic behavior, and the ground state is canted antiferromagnetic phase associated with uncompensated electron spins. In addition, the hydrogen evolution reaction performance was also studied. The present study compared the current densities (j), measured at the overpotential of $-372.8 \text{mV} \leq \eta \leq -169.6 \text{mV}$, listed from greatest to least, j(FeMoS2) = 4.05, j(CoMoS2) = 3.00, j(MoS2) = 2.09, j(NiMoS2) = 1.52 μA/cm². The order of overall reaction activity is obtained from Tafel slopes as CoMoS2 > MoS2 > NiMoS2 > FeMoS2 > MnMoS2. The electrochemical impedance spectroscopic measurements indicated that Fe doped MoS2 NCs have the best conductivity and charge transfer ability, while Mn-doped MoS2 NCs have the lowest. Co doped MoS2 NCs show best catalytic activity when compared to Mn doped MoS2 NCs. Most likely, it is due to the creation of a higher number of catalytically active centers in Co doped MoS2 NCs compared to Mn doped MoS2 NCs, as evidenced from room temperature ESR measurements.
